Renormalization, Large Deviations and Phase Separation in Ising and Percolation Models*

Ágoston Pisztora†

Abstract

Phase separation is a fairly common physical phenomenon with examples including the formation of water droplets from humid air (fog, rain), the separation of a crystalline structure from an isotropic material such as a liquid or even the formation of the sizzling gas bubbles when a soda can is opened.

It was recognized long ago (at least on a phenomenological level) that systems exhibiting several phases in equilibrium can be described with an appropriate variational principle: the phases arrange themselves in such a way that the energy associated with the phase boundaries is minimal. Typically this leads to an almost deterministic behavior and the phase boundaries are fairly regular. However, when looked at from a microscopic point of view, the system consists of a bunch of erratically moving molecules with relatively strong short-range interaction and the simplicity of the above macroscopic description looks more than miraculous. Indeed, when starting from the molecular level, there are many more questions to be asked and understood: which are the phases which we will see? why do only those occur? why are the phase boundaries sharp? how should we find (define) the energy associated with the interfaces? Only then can we ask the question: why does the system minimize this energy?

It is only in the last decade that a mathematically satisfactory understanding of this phenomenon has been achieved. The main goal of the talk is to present the current state of affairs focusing thereby on results obtained in joint works with Raphael Cerf. The connection to fields of mathematics other than probability theory or statistical mechanics will be highlighted; namely, to geometric measure theory and to the calculus of variations.

1. Introduction

Although phase separation is a fairly common physical phenomenon (examples will be given further below) its mathematically satisfactory understanding, even in the simplest models, has not been achieved until the last decade. In order to uncover the mechanism leading to the separation of various phases in an initially homogeneous material, in particular to explain why and what kind of phases will occur and which shapes they take, one has to work with a microscopic description of the system, often at a molecular scale. Materials on such scales however tend to behave 'chaotic' and this strongly motivates (if not compels) the use of a probabilistic approach. In this approach, the system is modeled by randomly moving (in equilibrium theory randomly located) particles which interact with each other according to some simple, typically short range, mechanism. The goal is then to derive the large scale behavior of the system based only on the specification of the local interaction.

The difficulty of the analysis stems from the fact that the interaction, although local, might be strong enough (depending on some parameter such as the temperature) to cause a subtile spatial propagation of stochastic dependence across the entire system. As a consequence, one has to leave the familiar realm of classical probability theory whose focus has been laid on the large scale effects of randomness arising from independent (or weakly dependent) sources. Instead, we have to deal with a strongly dependent system and it is exactly this strong dependence which causes a highly interesting cooperative behavior of the particles on the macroscopic level which can, in certain cases, be observed as phase separation.

The problem of phase separation and related issues have been a driving force behind developing, and a benchmark for testing various new techniques. Postponing historical remarks until section 2.1, let me highlight here only those ones which play an essential role in our approach [10, 11] achieved in collaboration with Raphael Cerf. The basic framework is *(abstract) large deviation theory*, see e.g. [37], whose power contributed substantially (admittedly rather to my own surprize) to the success of this approach. To have sufficient control of the underlying model, in our case the Ising-Potts model, we employ *spatial renormalization techniques*, as developed in [34], in conjunction with the Fortuin-Kasteleyn percolation representation of the Potts model, [21]. Finally, tools from geometric measure theory a la Cacciopoli and De Giorgi will be employed to handle the geometric difficulties associated with three or higher dimensions, in a similar fashion as was done in [9].

The goal of this article is to present some recent developments in the equilibrium theory of coexisting phases in the framework of the Ising-Potts model. The presentation will be based mainly on the results contained in [34, 10, 11]. It will include a description of the underlying physical phenomenon, of the corresponding mathematical model and its motivation and, following the statement of the main results, comments on the proofs will be included. In order to address an audience broader than usual, I will try to use as little formalism as possible.

1.1. Phase separation: examples and phenomenology

Perhaps the most common and well known example of phase separation is the development of fog and later rain from humid air. When warm humid air is cooled down so much that its *relative* humidity at the new cooler temperature would exceed 100% (i.e. it would become over-saturated) the excess amount of water precipitates first in the form of very small droplets which we might observe as fog. The system at this time is not in equilibrium, rather in a so called metastable state. After waiting very long time or simply dropping the temperature further down, the droplets grow bigger and ultimately fall to the ground due to gravitation in the form of common rain droplets. In this example phase separation occurred since from a single homogeneous phase (warm humid air) two new phases have been formed: a cooler mixture of water and air (note: with 100% relative humidity (saturated) at the new lower temperature) plus a certain amount of water, more precisely a saturated solution of air in water, in the form of macroscopic droplets. In fact, in the absence of gravitation and after very long time, only a huge droplet of fluid would levitate in a gas (both saturated solutions of air in water and water in air, respectively). The opposite situation (water majority, air minority) may also occur. Consider the following familiar example; think of a bottle of champagne when opened. Here the change of temperature is replaced by a change of pressure but the phenomenon is similar with the roles exchanged; at the new lower pressure the liquid is not able to dissolve the same amonunt of carbon dioxide, hence this latter precipitates in the form of small bubbles (droplets), etc.

The phenomenological theory explains this type of phenomenon as follows. At any temperature there are saturation densities of air/water and water/air mixtures and only saturated solutions will coexist in equilibrium. They also determine the volumes of the two coexisting phases. Moreover the phases arrange themselves in a way so as to minimize the so-called *surface energy*, associated with the interface between the phases. In fact, it is supposed to exist a (in general direction-dependent) scalar quantity τ, called the *surface tension*, whose surface integral along the interface gives the surface energy. The surface tension, as well as the saturation densities, have to be measured experimentally. It is implicitly assumed that the interface is 'surfacelike' and regular enough so that the integral along the surface makes sense. The prediction which can be made is that the shape of the phases in equilibrium is just a solution of the variational principle. By the classical isoperimetric theorem, in the isotropic case the solution is just a sphere, hence the occurrence of bubbles and droplets. In the non isotropic case the corresponding variational problem is called the *Wulff problem*. The solution is known to be explicitly given [38, 13, 19, 20, 36] by rescaling appropriately the so called *Wulff crystal:*

$$\mathcal{W}_\tau = \big\{ x \in \mathbb{R}^d \,;\, x \cdot \nu \le \tau(\nu) \text{ for all unit vectors } \nu \big\}.$$

It is worth noting that the same arguments are used to describe macroscopic crystal shapes as well.

1.2. The mathematical model and the goals of the analysis

The next step is to find a model which is simple enough to be analyzed by rigorous methods yet rich enough to exhibit the phenomenon we want to study.

In order to accommodate a multitude of phases we consider a finite number (q) possible types of particles (called colors or spins). Physics suggests to choose a short range interaction of "ferromagnetic" character which means that particles of identical type prefer to stay together and/or they repel particles of different types. For simplicity we assume that the interaction distinguishes only between identical and different types, otherwise it is invariant under permutation of colors. There is a standard model of statistical mechanics, called the (ferromagnetic) *q-states Potts model*, which corresponds exactly to these specifications. We consider the closed unit cube $\Omega \in \mathbb{R}^d$, $d \geq 3$ (modeling the container of the mixture of particles) overlapped by the rescaled integer lattice $\mathbb{Z}_n^d = \mathbb{Z}^d/n$. We define $\Omega_n = \Omega \cap \mathbb{Z}_n^d$, and denote by $\partial^{in}\Omega_n$ the internal vertex boundary of Ω_n. At each lattice point x there is a unique particle σ_x of one of the types $1, 2, ..., q$. The energy $H(\sigma)$ of a configuration $\sigma = (\sigma_x)_{x\in\Omega_n}$ can be chosen to be the number of nearest neighbor pairs of different types of particles corresponding to nearest neighbor repulsion. According to the Gibbs formula, the probability of observing a configuration σ is proportional to $e^{-\beta H(\sigma)}$, where $\beta = 1/T$ is the 'inverse temperature' which adjusts the interaction strength. (High T = large disorder = *relatively* small interaction, etc.) Note that we use a static description of the equilibrium system. It corresponds to a snap-shot of the system at a given time and the task is to understand the 'typical' picture we will see.

A *restricted ensemble* is a collection of certain feasible configurations. For instance, in the situation of the water/air mixture every configuration with a fixed number of water and air particles is possible, and this collection forms our restricted ensemble. It turns out that the direct study of this particular ensemble is extremely difficult and it is a crucial idea (discovered long ago) to go over to a larger, more natural ensemble, namely to that without any restrictions on the particle numbers. Then, the restricted system can be regarded as a very rare event =: G_n in the large ensemble and conditional probabilities can be used to describe the restricted system. The events G_n are often in the large deviations regime, and it is from here that large deviations theory enters the analysis in an essential way.

The unrestricted system is usually referred to as the Potts model with free boundary conditions. In the case $q = 2$, it is equivalent to the classical Ising model. The Gibbs formula and the energy uniquely determines the probability measure in this (and in every) ensemble. We can introduce mixed boundary conditions as follows. Divide the boundary $\Gamma = \partial\Omega$ of the 'container' into $q+1$ parts indexed by $\Gamma^0, \Gamma^1, ...\Gamma^q$. The parts can be fairly general but the $(d-1)$-dimensional Hausdorff measure of their relative boundaries has to be zero. We set for $n \in \mathbb{N}$ and $i = 0, \ldots, q$,

$$\Gamma_n^i \quad = \quad \left\{x \in \Gamma_n\,;\ \mathrm{d}_\infty\left(x, \Gamma^i\right) < 1/n \text{ and } \forall j < i,\ \mathrm{d}_\infty\left(x, \Gamma^j\right) \geq 1/n\right\} \qquad i = 0, \ldots, q$$

where d_∞ denotes the distance corresponding to the max-norm. We use the sequence of $q+1$-tuples of sets $\gamma(n) = (\Gamma_n^0, \ldots, \Gamma_n^q)$ to specify boundary conditions by imagining that all particles in Γ_n^j are of type j for $j = 1, ..., q$ and none occupies Γ_n^0. This defines a restricted ensemble and the corresponding probability measure is denoted by $\mu_n = \mu_n^{\gamma(n),\beta,q}$. The choice of b.c.s $\gamma(n)$ is understood to be fixed.

Let's consider the Ising-Potts model in an $n \times n$ lattice box $B(n)$ with boundary conditions $j \in \{1, 2, ..., q\}$ at a fixed inverse temperature β with the corresponding probability measure $\mu_{B(n)}^{(j),\beta}$. It is well known that, as $n \to \infty$, a unique, translation invariant infinite volume measure $\mu_{\infty}^{(j),\beta}$ emerges as the weak limit of the sequence $(\mu_{B(n)}^{(j),\beta})_{n\geq 1}$. We can define the *order parameter* $\theta = \theta(\beta, q, d)$ as the *excess density* of the dominant color, the excess is measured from the symmetric value $1/q$. The model exhibits phase transition in the sense that in dimensions $d \geq 2$ there exists a critical value $0 < \beta_c(d) < \infty$ such that for $\beta < \beta_c$, $\theta(\beta) := \mu_{\infty}^{(j),\beta}\big[\sigma_0 = j\big] - 1/q = 0$ but for $\beta > \beta_c$, $\theta(\beta) > 0$, i.e., when the interaction becomes strong enough, the influence of the (arbitrarily) far away boundary still propagates all the way through the inside of the volume and creates a majority of j-type particles. (Note that in the Ising model ($q = 2$), the spontaneous magnetization m^* is equal to θ.) The probability measures $\mu_{\infty}^{(j),\beta}$, $j = 1, 2, ..., q$, describe in mathematical terms what we call 'pure' phases and which correspond to the saturated solutions in the initial example.

Having chosen our model, let us formulate the goals of the analysis. Clearly, the main goal is to verify the predictions of the phenomenological theory, namely, that on the macroscopic scale the phases will be arranged according to some solution of the variational principle corresponding to minimal surface energy. First, however, the participating phases have to be found and identified. Moreover, as pointed out earlier, the previous statement contains a couple of implicit assumptions, such as the existence of the surface tension, the absence of transitional states (where one phase would smoothly go over into another one) the regularity of the interface boundaries, etc., all of which have to be justified from a microscopic point of view.

1.3. Connection to minimal surfaces

In this section a partially informal discussion of some examples will be presented with the aim to make the close relation to minimal surfaces transparent.

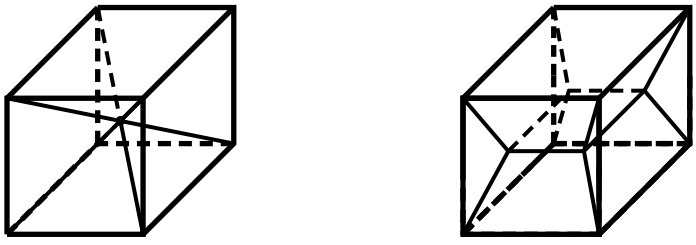

figure 1

Consider the Potts model with $q = 6$ colors (states) in a three dimensional box with boundary condition i on the i-th face of the box. Naively, one might expect that all phases will try to occupy the region closest to the corresponding piece of the boundary, which would lead to a phase partition consisting of symmetric and

pyramid-like regions, as can be seen in figure 1, left. However, at least in the case when the surface tension is isotropic (which is presumably the case in the limit $T \uparrow T_c$), there exists a better configuration with lower total surface free energy. Recall that in this case our desired interface is simply a minimal surface spanned by the edges of the box. A picture of the well known solution to this problem can be seen in figure 1, right. In order to be able to discuss this example at temperatures $0 < T < T_c$, we have to make certain assumptions about the surface tension τ. We assume that the sharp simplex inequality holds, that the value of τ is minimal in axis directions and that τ increases as the normal vector moves from say $(0, 0, 1)$ to $(1, 1, 1)$. (Although these assumptions are very plausible, none of them has been proved in dimensions $d \geq 3$). Under these hypotheses, we conjecture that the phase partition at moderate subcritical temperatures looks like in figure 2, left. In the limit $T \downarrow 0$, only two phases survive, as shown in figure 2, right. At $T = 0$, there is no reason for the middle plane to stay centered, in fact, any horizontal plane is equally likely.

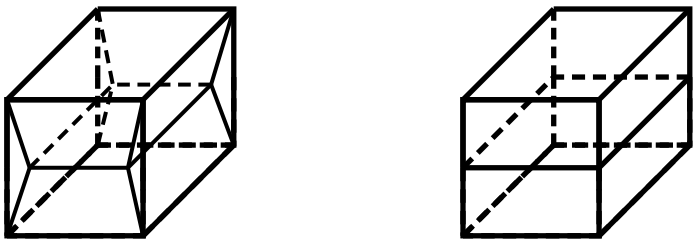

figure 2

In the next example we consider the three dimensional Ising model with free boundary conditions below T_c, conditioned on the event that the average magnetization is positive and does not exceed $m^* - \varepsilon$, where ε is a sufficiently small positive number and m^* denotes the spontaneous magnetization. It is natural to conjecture that a minimizer of the corresponding variational problem is a droplet attached symmetrically to one of the corners of the box.

The single bubble sitting in one of the corners is filled with the minus phase and in the rest of the box we see the plus phase. The size of the bubble is determined by ε and its internal boundary coincides with the corresponding piece of the surface of the Wulff crystal.

Another Wulff-type problem arises by conditioning the q-states Potts model (with say $q \geq 4$) to have a moderate excess of colors 2 and 3 while imposing 1-boundary conditions on the entire box. In this case it is conceivable that a so-called "double bubble" is created, consisting of two adjacent macroscopic droplets filled with the (pure) phases 2 and 3, respectively. The double bubble is swimming in the phase 1 which fills the rest of the box. Of course, we might have an excess of color 4 as well; in this case a further bubble will presumably appear which will be attached to the previous two bubbles.

For related variational questions concerning soap films and immiscible fluids, see [30].

In fact, by studying questions concerning phase boundaries we are very quickly confronted with the theory of minimal surfaces, such as the Plateau problem, corresponding to anisotropic surface measures. Let Ω be a bounded open set in $\mathbb{R}^3$ with smooth boundary and let γ be a Jordan curve drawn on $\partial\,\Omega$ which separates $\partial\,\Omega$ into two disjoint relatively open sets Γ^+ and Γ^-. Typical configurations in the Ising model on a fine grid in Ω with plus b.c.s on Γ^+ and minus b.c.s on Γ^- will exhibit two phases separated with an interface close to a minimal surface which is a global solution of the following Plateau type problem:

$$\text{minimize } \int_S \tau(\nu_S(x))\, d\mathcal{H}^{d-1}(x) \;:\; S \text{ is a surface in } \Omega \text{ spanned by } \gamma$$

where $\nu_S(x)$ is the normal vector to S at x. We remark that it is conjectured that, as the temperature approaches T_c from below, the surface tension τ becomes more and more isotropic and it is conceivable that the solution of the above minimization problem approaches the solution of the classical (isotropic) Plateau problem.

1.4. Further background

There is a beautiful and extremely useful way to decompose the Ising-Potts model into a certain bond percolation model, called FK-percolation and some simple 'coloring' procedure discovered by Fortuin and Kasteleyn [21]. Consider the q-state Potts model with mixed boundary conditions γ in a finite lattice box B at inverse temperature β and set $p = 1 - e^{-\beta}$. Consider a bond percolation model (called FK percolation) specified by the following formula:

$$\Phi_B^{\gamma,\beta,q}\big[\eta\big] = P_p[\eta]\, q^{\#(\eta)}/Z_B^{\gamma,\beta,q}$$

where η is a bond configuration with the property that there is no open connection between differently colored boundary parts, P_p is the usual Bernoulli measure with parameter p, $\#(\eta)$ denotes the number of clusters (conn. components) in the configuration η with the rule that identically colored boundary parts (and their connected components) count as one single cluster. Finally $Z_B^{\gamma,\beta,q}$ is the appropriate normalizing constant.

In the second step we assign colors to every cluster (and their sites) as follows: the boundary pieces inherit the color of the boundary condition, the remaining clusters will get one of the colors $1, 2, ..., q$ with probability $1/q$ each independently from each other. The distribution of the coloring of the sites corresponds exactly to the Potts model. Note that in the case of free or constant b.c.s. there is no constraint prohibiting open connections, and indeed these measures, denoted by $\Phi_B^{f,\beta,q}$ (free b.c.s.) and $\Phi_B^{w,\beta,q}$ ("wired" b.c.s.) behave very similar to regular Bernoulli percolation. Their thermodynamic limits $\Phi_\infty^{f,\beta,q}$ and $\Phi_\infty^{w,\beta,q}$ exist as the box size tends to infinity and we can define the percolation probability as usual $\theta^*(p) = \Phi_\infty^{*,p}\big[0 \leftrightarrow \infty\big]$, for $*$ free or wired. It is easy to check that the order parameter $\theta(\beta)$ of the Ising-Potts model agrees with $\theta^w(\beta)$, and correspondingly the FK model exhibits a percolation phase transition. Further it is known [23], that $\theta^w(\beta) = \theta^f(\beta)$ for all but at most countably many values of β and it is conjectured

that the equality is valid for all values except possibly the critical point $\beta_c = \beta_c(q)$. Moreover this condition is equivalent to the equality of the thermodynamical limits: $\Phi_\infty^{w,\beta,q} = \Phi_\infty^{f,\beta,q}$. We define the set of "regular" inverse temperatures by

$$\mathcal{U}(q) = \big\{\beta > 0\,;\, \theta^w(\beta) = \theta^f(\beta)\big\}.$$

Although the status of the bonds are dependent, their correlation tends fast to zero as the distance between them becomes large and this holds for both the sub and supercritical phase of FK percolation. This property is of crucial importance in our large deviation analysis since in the original Potts model there exists no corresponding asymptotic independence when $\beta > \beta_c$.

Our results are valid above the so called *slab-threshold* $\widehat{\beta}_c = \widehat{\beta}_c(q,d)$, introduced in [34]. This threshold is conjectured to agree with the critical point and at least in the case of percolation ($q = 1$) this have been proved by Grimmett and Marstrand [24]. It is possible to characterize this threshold as the smallest value such that when β exceeds it, it is possible to find $\alpha > 0$ and $L \geq 1$ such that at least in the center of the of slabs $S(L,n) = [-L,L] \times [-n,n]^{d-1} \cap \mathbb{Z}^d$ there is "uniform long range order", i.e.,

$$\inf_{n\geq 1} \inf_{x,y\in S(L,\alpha n)} \Phi_{S(L,n)}^{f,\beta}\Big[x \leftrightarrow y\Big] > 0.$$

It has been proved in [34] that above $\widehat{\beta}_c$, α always can be chosen to be one, guaranteeing a strictly positive probability (uniformly in n) for connections within a sufficiently (depending on β) thick slab. This property is crucial for establishing the basic properties of supercritical FK percolation; the existence of a unique crossing cluster in a box, its omnipresence, the concentration of its density around the percolation probability, the exponential tail decay of the diameter of other clusters in the box, etc. These properties are then used to establish a renormalization scheme which is essential for the large deviation analysis of this and the Ising-Potts model.

2. The results

2.1. Historical remarks

Before we start with the presentation of our results we give a brief summary of the previous work on this subject. As we have already mentioned, large deviations theory plays an important role in this context and not surprisingly the first efforts were devoted to the study of large deviations of the empirical magnetization in the Ising model, i.e., the average value of the spins in a large box. A *volume order* large deviation principle (LDP) has been established for the Ising model by various authors: Comets, Ellis, Föllmer, Orey, Olla [12, 15, 17, 32]. The corresponding rate function has been found to vanish in $[-m^*, m^*]$ where m^* denotes the spontaneous magnetization. In fact, it was suspected that the correct order of decay is exponential to *surface order*. Indeed, Schonmann [35] found a proof of this conjecture, valid for any dimensions and low enough temperatures and Chayes, Chayes and

Schonmann extended the result for the supercritical $\beta > \beta_c$ regime in the two dimensional case. Föllmer and Ort [18] investigated this phenomenon on the level of empirical measures. Finally, inspired by the work of Kesten and Zhang [29] on related questions in percolation, Pisztora [34] established surface order upper bounds for the remaining dimensions $d \geq 3$ above the slab-threshold $\widehat{\beta}_c$, introduced in the same work, which is conjectured to agree with the critical point β_c. In that work a renormalization scheme has been developed for supercritical Fortuin-Kasteleyn percolation (or random cluster model) in conjunction with a stochastic domination argument (generalized and improved in [31]) which allows to control the renormalized process, and so, the original one.

The monograph of Dobrushin, Kotecký and Shlosman [14] opened the way to the rigorous study of the phase separation phenomenon creating thereby an immense interest and activity which lasts up to the present time. Their analysis, which provided the first mathematical proof of phase separation, had been performed in the context of the Ising model. The main tool of their work is the cluster expansion, which, on the one hand allowed the derivation of results much finer than necessary to verify the Wulff construction, on the other hand it restricted the validity of the results to two dimensions and low temperatures. Significant improvements of these results in two dimensions have been derived by Pfister [33], Alexander, Chayes and Chayes [4] (treating percolation), Alexander [3], Ioffe [26, 27]. Finally Ioffe and Schonmann [28] extended the results of [14] up to T_c.

The next challenge was to analyze phase separation for short range models in higher dimensions. The additional difficulties came mainly from two sources. First, new techniques have to be developed to avoid the use of perturbative methods (such as the cluster expansion) which severely limit the applicability of the arguments and methods which are specific to two dimensions only (duality). Second, the emerging geometry is far more complex than in two dimensions and this requires the use of new tools and ideas. The complexity of the geometry causes problems also within the probabilistic analysis (for instance the lack of the skeleton technique for surfaces) and even the correct formulation of the results is far from obvious ("hairs").

The first issue has been resolved by the application of the aforementioned renormalization technology from [34]. Renormalization arguments lie at the heart of the proof of much of the intermediate steps (for instance exponential tightness, decoupling) and even in the remaining parts they play an important role usually in combination with geometric arguments (interface lemma, etc.).

To handle the geometric difficulties, the use of appropriate tools from geometric measure theory has been introduced in the works of Alberti, Bellettini, Bodineau, Buttà, Cassandro, Presutti [2, 5, 6] and by Cerf [9]. In these works also a novel and very general large deviation framework have been proposed to tackle the problem. In fact, this framework turned out to be crucial for the success of the entire approach. It is the work of Cerf [9] in which the first complete analysis of phase separation in a three dimensional model have been achieved, namely the asymptotic analysis of the shape of a large finite cluster (Wulff problem) in percolation.

The results presented in this article have been derived in the works [34, 9, 10, 11]. It should be mentioned that in an independent work [7] Bodineau carried out

an analysis of the Wulff problem in the Ising model with conclusions slightly weaker than the results appearing in [10].

Finally, for current developments in the field we refer the reader to the preprint [8] and the references therein.

2.2. Statement of the results

Range of validity of the results. Our results for the Ising-Potts models hold in the region: $d \geq 3,\ q \in \mathbb{N} \setminus \{0,1\},\ \beta > \widehat{\beta}_c(q,d),\ \beta \in \mathcal{U}(q,d)$.

At this point it is natural to comment on the case of two dimensions. Although most of our results should hold for $d = 2$, there are several points in the proofs which would require a significant change, making the proofs even longer. The main reason, however, for not to treat the two dimensional case is that the natural topology for the LDP-s in $d = 2$ is not the one we use (which is based on the distance $\mathrm{dist}_{\mathrm{L}^1}$) but a topology based on the Hausdorff distance.

Surface tension. From FK percolation we can extract a direction dependent surface tension $\tau(\nu) = \tau(p,q,d,\nu)$, cf [10]. For a unit vector ν, let A be a unit hypersquare orthogonal to ν, let $\operatorname{cyl} A$ be the cylinder $A + \mathbb{R}\nu$, then $\tau(\nu)$ is equal to the limit

$$\lim_{n\to\infty} -\frac{1}{n^{d-1}} \log \Phi_\infty^{p,q} \begin{pmatrix} \text{inside } n \operatorname{cyl} A \text{ there exists a finite set of closed edges } E \\ \text{cutting } n \operatorname{cyl} A \text{ in at least 2 unbounded components and} \\ \text{the edges of } E \text{ at distance less than } 2d \text{ from the boundary} \\ \text{of } n \operatorname{cyl} A \text{ are at distance less than } 2d \text{ from } nA \end{pmatrix}$$

The function τ satisfies the weak simplex inequality, is continuous, uniformly bounded away from zero and infinity and invariant under the isometries which leave $\mathbb{Z}^d$ invariant (see section 4 in [10] for details).

Identification of the phases. The typical picture which emerges from the Potts model with mixed b.c.s. at the macroscopic level is a partition of Ω in maximal q phases corresponding to the dominant color in that phase. The individual phases need not be connected. In order to identify the phases we choose first a sequence of *test events* which we regard as characteristic for that phase. More specificly, for $j = 1, 2, ..., q$ we select events $E_n^{(j)}$ defined on a $n \times n$ lattice box such that $\mu_\infty^{(j),\beta,q}\big[E_n^{(j)}\big] \to 1$ as $n \to \infty$. We may also assume that $E_n^{(j)} \cap E_n^{(j)} = \emptyset$ for $j \neq i$. For instance, one natural choice is to require that the densities of the different colors in the box do not deviate more than some small fraction from their expected value. This will guarantee that the right mixture of colors occurs which is typical for that particular pure phase. Alternately, we may request that the empirical measure defined by the given configuration is close to the restriction of $\mu_\infty^{(j),\beta,q}$ to $\Lambda(n)$ with respect some appropriate distance between probability measures, etc.

For $x \in \mathbb{R}^d$ and $r > 0$ we define the box $\Lambda(x,r)$ by

$$\Lambda(x,r) = \Big\{ y \in \mathbb{R}^d;\ -r/2 < y_i - x_i \leq r/2,\ i = 1, \ldots, d \Big\}$$

and we introduce an *intermediate length scale* represented by a fixed function f :

$\mathbb{N} \to \mathbb{N}$ satisfying

$$\lim_{n\to\infty} n/f(n)^{d-1} = \lim_{n\to\infty} f(n)/\log n = \infty. \tag{1}$$

Given a configuration in Ω_n, we say that the point $x \in \Omega$ belongs to the phase j, if the event $E_n^{(j)}$ occurs in the box $\Lambda(x, f(n)/n)$. For $j = 1, 2, .., q$, we denote by $A_n^{(j)}$ the set of points in Ω belonging to the phase j and set $A_n^{(0)} = \Omega \setminus \cup_j A_n^{(j)}$ (indefinite phase).

The random partition of Ω, $\vec{A}_n = (A_n^0, A_n^1, \ldots, A_n^q)$, is called the *empirical phase partition*. Our first result shows that up to super-surface order large deviations, the region of indefinite phase A_n^0 has negligible density, i.e., the pure phases fill out the entire volume.

Theorem 2.1 *Let $d \geq 3$, $q \in \mathbb{N} \setminus \{0, 1\}$, $\beta > \widehat{\beta}_c$, $\beta \in \mathcal{U}(q, d)$. For $\delta > 0$,*

$$\limsup_{n\to\infty} \frac{1}{n^{d-1}} \log \mu_n\big[\,\mathrm{vol}\,(A_n^0) > \delta\big] = -\infty.$$

Although Theorem 2.1 guarantees that the pure phases fill out the entire volume (up to negligible density) but it does not exclude the possibility that the connected components of the pure phases are very small. For instance, they could have a diameter not much larger than our fixed intermediate scale (in which case they would be invisible on a macroscopic scale.) If this happened, the total area of the phase boundaries would be exceedingly high. Before stating our next result, which will exclude this possibility, we introduce some geometric tools.

We define a (pseudo) metric, denoted by $\mathrm{dist}_{\mathrm{L}^1}$, on the set $\mathcal{B}(\Omega)$ of the Borel subsets of Ω by setting

$$\forall A_1, A_2 \in \mathcal{B}(\Omega) \qquad \mathrm{dist}_{\mathrm{L}^1}(A_1, A_2) \;=\; \mathrm{vol}\,(A_1 \Delta A_2). \tag{2}$$

We consider then the *space of phase partitions* $P(\Omega, q)$ consisting of $q+1$-tuples $(A^0, A^1, \ldots, A^q)$ of Borel subsets of Ω forming a partition of Ω. We endow $P(\Omega, q)$ with the following metric:

$$\mathrm{dist}_P\Big((A^0, \ldots, A^q), (B^0, \ldots, B^q)\Big) = \sum_{i=0,\ldots,q} \mathrm{dist}_{\mathrm{L}^1}(A^i, B^i).$$

In order to define the surface energy $\mathcal{I}$ of a phase partition $\vec{A}_n$, we recall some notions and facts from the theory of sets of finite perimeter, introduced initially by Caccioppoli and subsequently developed by De Giorgi, see for instance [22, 16]. The perimeter of a Borel set E of $\mathbb{R}^d$ is defined as

$$\mathcal{P}(E) \;=\; \sup\Big\{ \int_E \mathrm{div}\, f(x)\, dx : f \in C_0^\infty(\mathbb{R}^d, B(1)) \Big\}$$

where $C_0^\infty(\mathbb{R}^d, B(1))$ is the set of the compactly supported C^∞ vector functions from $\mathbb{R}^d$ to the unit ball $B(1)$ and div is the usual divergence operator. The set E is

of finite perimeter if $\mathcal{P}(E)$ is finite. A unit vector ν is called the measure theoretic exterior normal to E at x if

$$\lim_{r\to 0} r^{-d}\,\mathrm{vol}\,(B_-(x,r,\nu)\setminus E) \;=\; 0\,, \quad \lim_{r\to 0} r^{-d}\,\mathrm{vol}\,(B_+(x,r,\nu)\cap E) \;=\; 0\,.$$

Let E be a set of finite perimeter. Then there exists a certain subset of the topological boundary of E, called the *reduced boundary*, denoted by $\partial^* E$, with the same $d-1$ dimensional Hausdorff measure as ∂E, such that at each $x\in\partial^* E$ there is a measure theoretic exterior normal to E at x. For practical (measure theoretic) purposes, the reduced boundary represents the boundary of any set of finite perimeter, for instance, the following generalization of Gauss Theorem holds: For any vector function f in $C_0^1(\mathbb{R}^d,\mathbb{R}^d)$,

$$\int_E \mathrm{div}\, f(x)\,dx \;=\; \int_{\partial^* E} f(x)\cdot\nu_E(x)\,\mathcal{H}^{d-1}(dx)\,.$$

(For more on this see e.g. the appendix in [10] and the references there.)

The *surface energy* $\mathcal{I}$ of a phase partition $(A_n^0 A_n^1,\dots,A_n^q)\in P(\Omega,q)$ is defined as follows:

- for any $(A^0,A^1,\dots,A^q)$ such that either $A^0\neq\emptyset$ or one set among $A^1,\dots,A^q$ has not finite perimeter, we set $\mathcal{I}(A^0,\dots,A^q)=\infty$,
- for any $(A^0,A^1,\dots,A^q)$ with $A^0=\emptyset$ and $A^1,\dots,A^q$ having finite perimeter, we set

$$\begin{aligned}\mathcal{I}(A^0,\dots,A^q) \;&=\; \sum_{i=1,\dots,q}\frac{1}{2}\int_{\partial^* A^i\cap\Omega}\tau(\nu_{A_i}(x))\,d\mathcal{H}^{d-1}(x)\\ &\quad+\sum_{\substack{i,j=1,\dots,q\\ i\neq j}}\int_{\partial^* A^i\cap\Gamma^j}\tau(\nu_{A_i}(x))\,d\mathcal{H}^{d-1}(x).\end{aligned}$$

Note that $\mathcal{I}$ depends on τ and the boundary conditions $\gamma=(\Gamma^1,...,\Gamma^q)$. The first term in the above formula corresponds to the interfaces present in Ω, while the second term corresponds to the interfaces between the elements of the phase partition and the boundary Γ. It is natural to define the *perimeter of the phase partition* by using the same formula with τ replaced by constant one. Since τ is uniformly bounded away from zero and infinity at any temperature, the surface energy can be bounded by a multiple of the perimeter and vice versa. It is known that the surface energy $\mathcal{I}$ and the perimeter $\mathcal{P}$ are lower semi continuous and their level sets of the form $\mathcal{I}^{-1}[0,K]$ are compact on the space $(\mathcal{B}(\mathbb{R}^d),\,\mathrm{dist}_{\mathrm{L}^1})$.

The next result states that up to surface order large deviations (and the constant can be made arbitrarily large by adjusting the bound K below) the empirical phase partition will be (arbitrarily) close to the set of phase partitions with perimeter not exceeding K.

Theorem 2.2 *Let $d\geq 3$, $q\in\mathbb{N}\setminus\{0,1\}$, $\beta>\widehat{\beta}_c$, $\beta\in\mathcal{U}(q,d)$. For $\delta>0$,*

$$\limsup_{n\to\infty}\frac{1}{n^{d-1}}\,\log\,\mu_n\Big[\,\mathrm{dist}_P(\vec{A}_n,\,\mathcal{I}^{-1}[0,K])>\delta\Big]\leq -c\,K.$$

Our fundamental result is a large deviation principle (LDP) for the empirical phase partition $(A_n^0, A_n^1, \ldots, A_n^q)$.

Theorem 2.3 *The sequence* $\big(\vec{A}_n\big)_{n\in\mathbb{N}} = \big((A_n^0, A_n^1, \ldots, A_n^q)\big)_{n\in\mathbb{N}}$ *of the empirical phase partitions of* Ω *satisfies a LDP in* $(P(\Omega,q), \mathrm{dist}_P)$ *with respect to* μ_n *with speed* n^{d-1} *and rate function* $\mathcal{I} - \min_{P(\Omega,q)} \mathcal{I}$*, i.e., for any Borel subset* $\mathbb{E}$ *of* $P(\Omega,q)$*,*

$$\begin{aligned} -\inf_{\substack{o\\ \mathbb{E}}} \mathcal{I} + \min_{P(\Omega,q)} \mathcal{I} &\leq \liminf_{n\to\infty} \frac{1}{n^{d-1}} \log \mu_n\Big[\vec{A}_n \in \mathbb{E}\Big] \\ &\leq \limsup_{n\to\infty} \frac{1}{n^{d-1}} \log \mu_n\Big[\vec{A}_n \in \mathbb{E}\Big] \\ &\leq -\inf_{\overline{\mathbb{E}}} \mathcal{I} + \min_{P(\Omega,q)} \mathcal{I}. \end{aligned}$$

Note that the constant $\min_{P(\Omega,q)} \mathcal{I}$ is always finite. Every large deviation result includes a (weak) law of large numbers; here the corresponding statement is as follows: Asymptotically, the empirical phase partition will be concentrated in an (arbitrarily) small neighborhood of the set of partitions minimizing the surface energy. In other words, on the macroscopic level, the typical phase partition will coincide with some of the minimizers of the variational problem, in agreement with the phenomenological prediction. Of course, the LDP states much more than this, in particular we will be able to extract similar statements for restricted ensembles. Recall that imposing mixed boundary conditions is not the only way to force the system to exhibit coexisting phases. In the Wulff problem in the Ising model context, for instance, a restricted ensemble is studied which is characterized by an artificial excess of say minus spins in the plus phase. Technically this can be achieved by conditioning the system to have a magnetization larger than the spontaneous magnetization while imposing plus b.c.s.

The next result describes the large deviation behavior of the phase partition in a large class of restricted ensembles. Although it is a rather straightforward generalization of Theorem 2.3, we state it separately because of its physical relevance.

Let $(G_n)_{n\geq 1}$ be a sequence of events, i.e., sets of spin configurations, satisfying the following two conditions: first there exists a Borel subset $\mathbb{G}$ of $P(\Omega,q)$ such that the sequence of events $(G_n)_{n\in\mathbb{N}}$ and $(\{\vec{A}_n \in \mathbb{G}\})_{n\in\mathbb{N}}$ are exponentially equivalent, i.e.,

$$\limsup_{n\to\infty} \frac{1}{n^{d-1}} \log \mu_n\Big[G_n \triangle \{\vec{A}_n \in \mathbb{G}\}\Big] = -\infty, \tag{3}$$

where $\triangle$ denotes the symmetric difference. Second, the following limit exists and is finite:

$$\mathcal{I}_G = \lim_{n\to\infty} \frac{1}{n^{d-1}} \log \mu_n[G_n] > -\infty. \tag{4}$$

The sequence of events $(G_n)_{n\geq 1}$ determines a restricted (conditional) ensemble. Note that if

$$\inf_{\substack{o\\ \mathbb{G}}} \mathcal{I} = \inf_{\overline{\mathbb{G}}} \mathcal{I} > -\infty, \tag{5}$$

then Theorem 2.3 implies that (4) is satisfied, with $\mathcal{I}_G = \inf_{\mathbb{G}} \mathcal{I}$.

Theorem 2.4 *Assume that the sequence $(G_n)_{n\geq 1}$ satisfies (3) and (4) and define for each $n \geq 1$ the conditional measures*

$$\mu_n^G = \mu_n(\,\cdot\,|G_n).$$

Then the sequence $\left(\vec{A}_n\right)_{n\geq 1}$ of the empirical phase partitions of Ω satisfies a LDP in $(P(\Omega,q),\,\mathrm{dist}_P)$ with respect to μ_n^G with speed n^{d-1} and rate function $\mathcal{I}-\mathcal{I}_G$, i.e., for any Borel subset $\mathbb{E}$ of $P(\Omega,q)$,

$$\begin{aligned} -\inf_{\mathbb{E}^o\cap\mathbb{G}} \mathcal{I}+\mathcal{I}_G &\leq \liminf_{n\to\infty} \frac{1}{n^{d-1}}\,\log\,\mu_n^G\Big[\vec{A}_n\in\mathbb{E}\Big] \\ &\leq \limsup_{n\to\infty} \frac{1}{n^{d-1}}\,\log\,\mu_n^G\Big[\vec{A}_n\in\mathbb{E}\Big] \\ &\leq -\inf_{\overline{\mathbb{E}}\cap\mathbb{G}} \mathcal{I}+\mathcal{I}_G. \end{aligned}$$

Theorem 2.4 gives a rigorous verification of the basic assumption underlying the phenomenological theory, namely, that in a given ensemble, the typical configurations are those minimizing the surface free energy. A general compactness argument implies the existence of at least one such minimizer. However, in most examples one cannot say much about the minimizers themselves. (One notable exception is the Wulff problem.) The difficulty stems from the fact that the surface tension τ is anisotropic and almost no quantitative information about its magnitude is available. Moreover, the corresponding variational problems are extremely hard even in the isotropic case and the (few) resolved questions represent the state of the art in the calculus of variations. For instance, a famous conjecture related to the symmetric double-bubble in the three dimensional case with isotropic surface energy (perimeter) has only been resolved recently [25] and the asymmetric case remains unresolved (even in the isotropic case).

We show next how Theorem 2.4 can be applied to the Wulff and multiple bubble problem. We take pure boundary conditions with color 1, that is, $\Gamma^1=\Gamma$, $\Gamma^2=\cdots=\Gamma^q=\emptyset$. Let $s_2,\cdots,s_q$ be $q-1$ real numbers larger than or equal to $(1-\theta)/q$. We set

$$\forall i\in\{2,\ldots,q\} \qquad v_i \;=\; \mathrm{vol}\,(\Omega)\theta^{-1}(s_i-(1-\theta)/q).$$

We define next the events

$$\forall n\in\mathbb{N} \qquad G_n \;=\; \{\forall i\in\{2,\ldots,q\} \quad \mathcal{S}_n(i)\geq s_i\}$$

and the collection of phase partitions

$$\mathbb{G}(v_2,\ldots,v_q)=\{\,\vec{A}=(A_0,A_1,\ldots,A_q)\in P(\Omega,q):\,\mathrm{vol}\,(A_2)\geq v_2,\ldots,\,\mathrm{vol}\,(A_q)\geq v_q\,\}.$$

It can be shown that the sequences of events

$$(G_n)_{n\in\mathbb{N}} \qquad \text{and} \qquad (\vec{A}_n\in\mathbb{G}(v_2,\ldots,v_q))_{n\in\mathbb{N}}$$

are exponentially equivalent, i.e., they satisfy the condition (3). In order to ensure condition (5), we suppose that the minimum of the surface energy $\mathcal{I}$ over $\mathbb{G}(v_2,\dots,v_q)$ is reached with a phase partition having no interfaces on the boundary Γ. More precisely, we suppose that the following assumption is fulfilled.

Assumption. The region Ω and the real numbers $v_2,\dots,v_q$ are such that there exists $\vec{A}^* = (A_0^*, A_1^*, \dots, A_q^*)$ in $\mathbb{G}(v_2,\dots,v_q)$ such that

$$\mathcal{I}(\vec{A}^*) \;=\; \min\{\,\mathcal{I}(\vec{A}); \vec{A} \in \mathbb{G}(v_2,\dots,v_q)\,\}$$
$$\forall i \in \{\,2,\dots,q\,\} \qquad d_2(A_i^*,\Gamma) > 0.$$

We expect that this assumption is fulfilled provided the real numbers $v_2,\dots,v_q$ are sufficiently small (or equivalently, $s_2,\dots,s_q$ are sufficiently close to $(1-\theta)/q$), depending on the region Ω. This is for instance the case when $q=2$. Indeed, let $\mathcal{W}_\tau$ be the Wulff crystal associated to τ. We know that $\mathcal{W}_\tau$ is, up to dilatations and translations, the unique solution to the anisotropic isoperimetric problem associated to τ. For v_2 sufficiently small, a dilated Wulff crystal $x_0+\alpha_0\mathcal{W}_\tau$ of volume v_2 fits into Ω without touching Γ, and the phase partition $\vec{A}^* = (\emptyset, \Omega\setminus(x_0+\alpha_0\mathcal{W}_\tau), x_0+\alpha_0\mathcal{W}_\tau)$ answers the problem. In the case $q>2$, we expect that a minimizing phase partition corresponds to a multiple bubble having $q-1$ components.

Under the above assumption, we claim that the collection of phase partitions $\mathbb{G}(v_2,\dots,v_q)$ satisfies (5). For $\lambda > 1$, we define

$$\vec{A}^*(\lambda) = \Big(\emptyset, \Omega \setminus \bigcup_{2\le i\le q} \lambda A_i^*, \lambda A_2^*, \dots, \lambda A_q^*\Big).$$

Since by hypothesis the sets $A_2^*,\dots,A_q^*$ are at positive distance from Γ, for λ larger than 1 and sufficiently close to 1, the phase partition $\vec{A}^*(\lambda)$ satisfies

$$\vec{A}^*(\lambda) \;\in\; \mathbb{G}(\lambda^d v_2,\dots,\lambda^d v_q) \;\subset\; \overset{\circ}{\mathbb{G}}(v_2,\dots,v_q)$$

and moreover $\mathcal{I}(\vec{A}^*(\lambda)) = \lambda^{d-1}\mathcal{I}(\vec{A}^*)$. Sending λ to 1, and remarking that $\mathbb{G}(v_2,\dots,v_q)$ is closed, we see that $\mathbb{G}(v_2,\dots,v_q)$ satisfies (5). Thus we can apply Theorem 2.4 with the sequence of events $(G_n)_{n\in\mathbb{N}}$, thereby obtaining a LDP and a weak law of large numbers for the conditional measures $\mu_n^G = \mu_n(\,\cdot\,|G_n)$. In the particular case $q=2$, we obtain again the main result (Wulff problem) of our previous paper [10]. In the more challenging situations $q>2$, the unresolved questions concerning the macroscopic behavior of such systems belong to the realm of the calculus of variations.
